Introduction to Multi-threaded Processor Verification

Development and Verification Needs

Rapid Growth of AI and Chip Architectures

with the surge of AI, multi-threading in computing has become crucial. It enhances performance but complicates verification, making system-level verification indispensable.

Traditional verification methods fail to meet modern demands due to the dynamic and uncertain nature of real-world applications.

Challenges in System-Level Verification

System- level verification generates realistic stimuli, covering all core pipeline modules. However, creating random and valid stimuli for multithreaded processors is a significant challenge.

Engineers struggle with intricate interactions like memory access synchronization and avoiding infinite

Importance of Efficient Verification

Efficient verification is vital for timely chip tapeout and reducing failure rates. It ensures that processors meet design specifications and perform reliably in various scenarios.

The proposed method aims to address these challenges by offering a versatile and highly random system-level verification approach.

Contributions of the Proposed Method

This paper introduces a system-level random stimulus generation framework using instruction-set modeling. Key innovations include modular API encapsulation for flexible instruction configuration and an automated multi-threaded conflict resolution mechanism to ensure reliability. The framework employs hierarchical constraints to balance randomness with legal instruction flow boundaries, enabling efficient and controlled test stimulus generation for processor verification.

Enhanced Debugging Support

A closed-loop debug support mechanism is established, integrating stimulus generation and debugging.

This significantly reduces debugging costs for complex instruction streams and improves defect localization efficiency.

Practicality and Effectiveness

Extensive experiments demonstrate the method's ability to uncover previously undetected design flaws.

It shows significant improvements in verification efficiency and comprehensive coverage of the instruction set architecture.

Hierarchical Structure

The proposed framework consists of four layers: Software Toolchain Layer, Instruction Set Abstraction Layer, Instruction Stream Randomization Layer, and Debugging Support Layer.

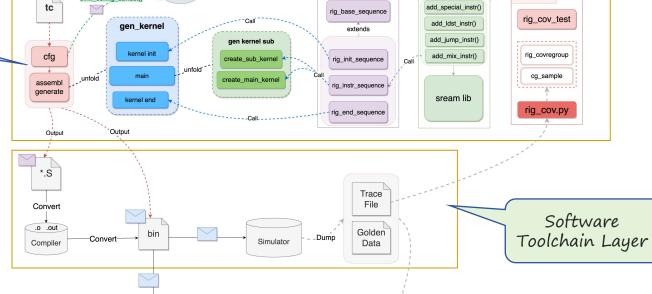

This hierarchical structure ensures seamless integration of instruction generation, randomization, and debugging Collaboration of Layers

The Software Toolchain Layer manages the entire process of instruction stream stimuli, from conversion to simulation verification.

The Instruction Set Abstraction Layer formalizes instruction semantics, enabling structured expression and randomization.

Key Components

The Instruction Stream Randomization Layer encapsulates APIs for generating diverse instruction types and formats. The Debugging Support Layer provides critical tools for tracing and diagnosing errors in complex instruction streams.

DUT

UVM ENV

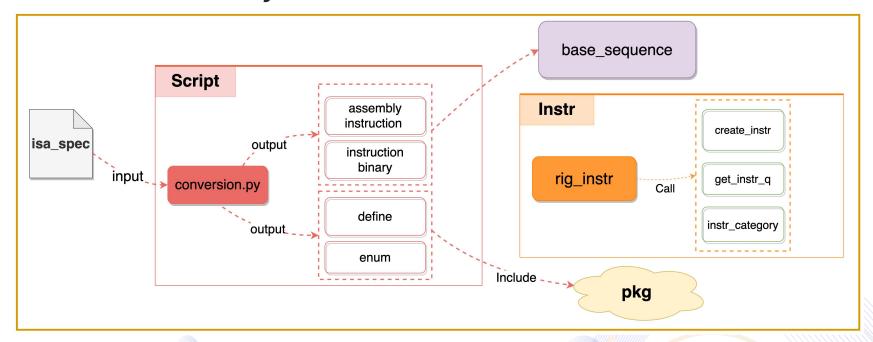

Checker

Instruction Set Abstraction Layer

Formalizing Instruction Semantics

The core objective of this layer is to formalize the semantics of the instruction set, providing manipulable variables for randomization. It categorizes the ISA into clusters such as computational, control, memory, and system instructions, defining their opcodes, operand constraints, and special field parameters.

Dynamic Instruction Object Generation

The UVM factory pattern dynamically generates instruction objects based on the defined ISA specifications.

The VCS constraint solver ensures operand legality, avoiding issues like writes to reserved registers.

Assembly Instruction Generation

Instantiated instruction objects are converted into target assembly syntax using a stringification engine.

This process enables the generation of diverse and valid instruction streams for system-level verification.

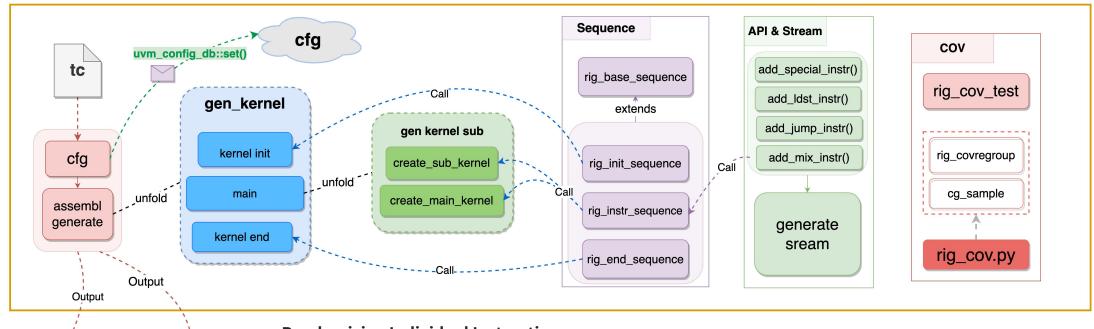

Instruction Stream Randomization Layer

Randomizing Individual Instructions

This layer aims to randomize individual instructions and construct instruction stream stimuli.

It encapsulates the instruction stream logic into multiple API functions, allowing customization of desired instruction types and formats.

API-Driven Instruction Generation

The APIs enable automated synchronization of memory access instructions and dynamic insertion of branch instructions. They also simplify instruction mixing and type weighting, facilitating the generation of mixed instruction types for multi-threaded processors.

Maintaining Instruction Stream Records

The framework maintains records of generated instruction streams, which is crucial for debugging and tracing errors. This ensures that the verification process is traceable and any issues can be quickly identified and resolved.

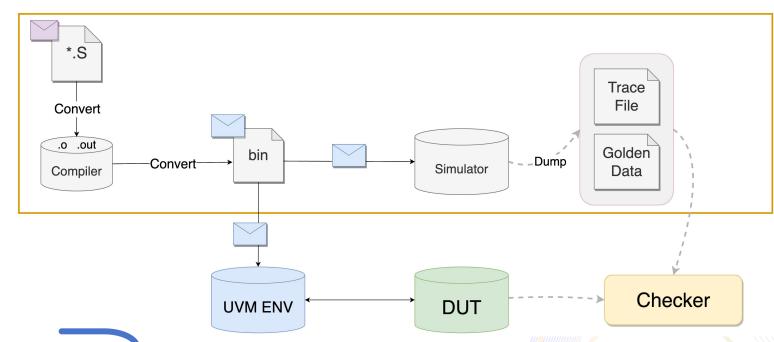

Software Toolchain Layer

01

Instruction Stream Management

This layer focuses on managing the conversion of instruction stream stimuli and the simulation process of simulators, ensuring smooth integration with the TUVM environment.

It supports syntax parsing of Instruction Set
Architecture (ISA) and converts the generated
instruction stream into binary files for simulation.

$02 \\ \\ \hbox{Integration with UVM Environment}$

The integrated software toolchain includes assembler and simulator interfaces, facilitating the conversion of instruction streams into binary format.

This seamless integration enables efficient verification of the Pesign Under Test (DUT) against specification expectations.

03 Golden Data Dump

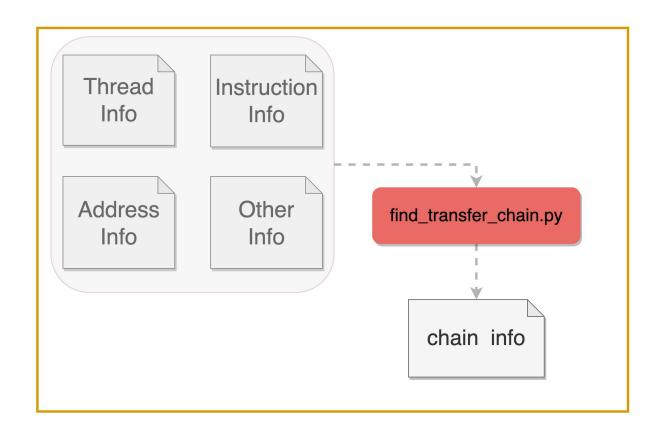

The binary files generated from instruction streams serve as golden data for dynamic simulation.

This ensures that the DUT's behavior aligns with the expected specifications, enhancing the reliability of the verification process.

Debugging Support Layer

Critical Debugging Tools

This layer provides essential tools for debugging complex instruction stream stimuli.

It includes mechanisms for identifying faulty threads and tracing back through the instruction stream to locate erroneous instructions.

Improving Debugging Efficiency

By leveraging recorded debug information, the debugging subsystem can quickly pinpoint the root cause of errors.

This significantly reduces the time and effort required for debugging, enhancing overall verification efficiency.

Visualizing Dependency Chains

The debugging support layer also visualizes dependency chains across threads, providing a clear understanding of the relationships between instructions.

This helps in diagnosing complex issues such as cache coherence problems and memory access conflicts.

API encapsulation and instruction flow constraints

API Functions

This API specializes in generating load/store (memory access) instructions.

It internally models an address management and synchronization mechanism to avoid cache coherence issues in multi-threaded processors.

This API randomly inserts instructions into existing instruction streams.

It allows users to specify the number of instructions to insert, the starting position, and the instruction queue.

add_ldst_instr()

add_mix_instr()

add_specific_instr()

This embedded API serves as the foundation for instruction generation in the instruction stream. It provides users with interfaces for configuring

instruction types, registers, and special instruction

fields while balancing high reusability and randomness.

This API handles the insertion of branch/jump instructions. It ensures that random jumps adhere to constraints such as legal jump ranges and avoiding jumps into synchronization regions.

add_jump_instr()

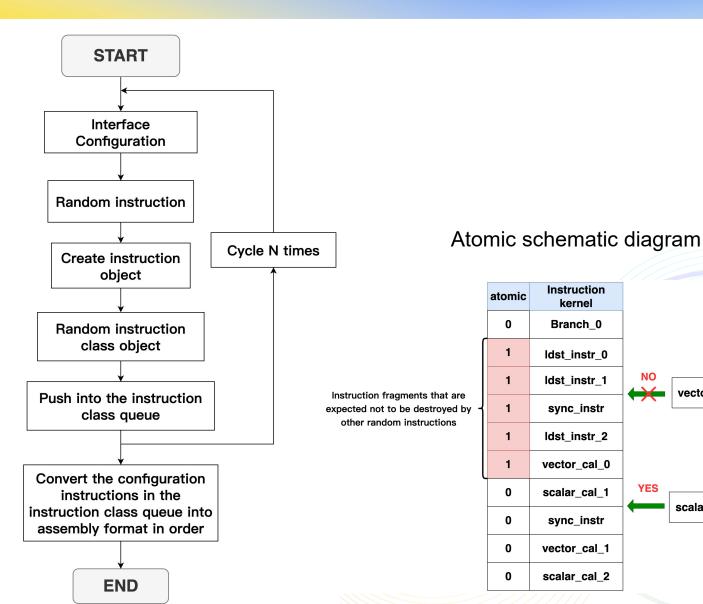

Basic API - add_specific_instr()

API Interface

- Instruction queue
- Register interface(vector register/scalar register/special register/immediate)
- Functional configuration args for special instructions
- Instruction comment
- Jump instruction target instruction label
- Atomic switch between instructions
- Interface fully configured check switch

vector cal 3

scalar_cal_3

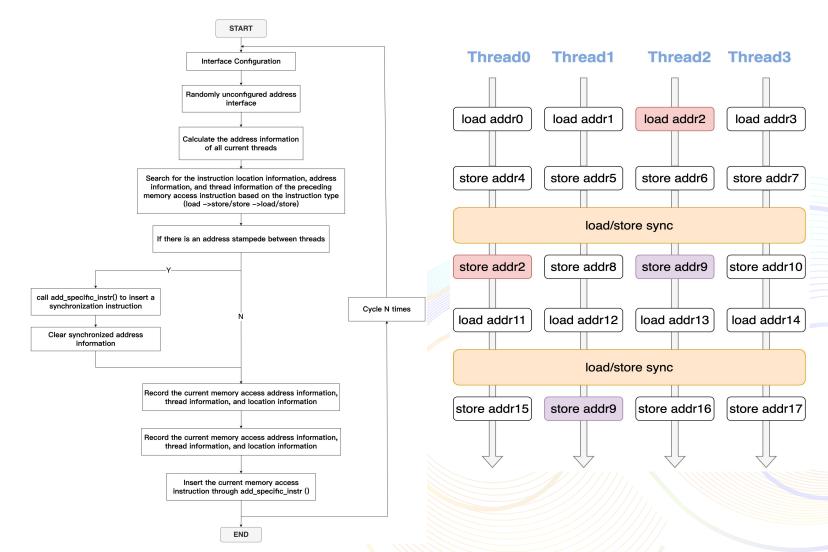

Load/Store instruction API - add_ldst_instr()

API Interface

- Load/Store instruction queue
- Saved address register
- offset address
- exception insert switch

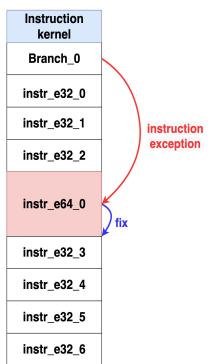

Jump instruction API - add_jump_instr()

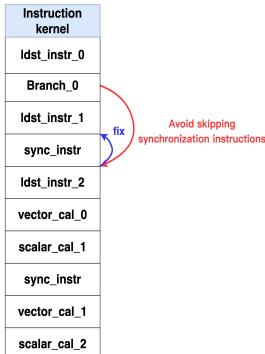

API Interface

- **Instruction queue**
- **Instruction count**
- **Starting instruction stream** index
- The maximum jump range for jump instructions

Constrained jump range within a reasonable range

_	atomic	Instruction kernel	
	0	Branch_0	
	1	ldst_instr_0	
	1	ldst_instr_1	
	1	sync_instr	inse
	1	ldst_instr_2	
	1	vector_cal_0	
	0	scalar_cal_1	
	0	sync_instr	
	0	vector_cal_1	
	0	scalar_cal_2	

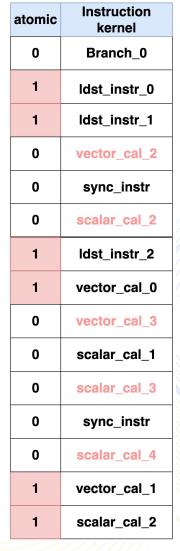

Mix instruction API - add_mix_instr()

API Interface

- Instruction queue
- Instruction count
- Starting instruction stream index

akant tandan	atomic	Instruction kernel
start_index	0	Branch_0
	1	ldst_instr_0
vector cal 2 →	1	ldst_instr_1
scalar cal 2	0	sync_instr
	1	ldst_instr_2
vector cel 2	1	vector_cal_0
vector_cal_3 → scalar cal 3 →	0	scalar_cal_1
scalar_cal_4	0	sync_instr
oodidi_odi_+	1	vector_cal_1
	1	scalar_cal_2

Instruction Stream Constraints

Hierarchical Constraint Mechanism

The API interfaces ensure instruction legality through a hierarchical constraint mechanism.

This includes mandatory constraints that serve as the baseline for legal instruction streams and user-configurable constraints for specific verification scenarios.

User-Configurable Constraints

Examples of user- configurable constraints include address legality control, customizable jump range settings, and address exception trigger. These constraints allow users to tailor the instruction streams to meet specific verification requirements and test various edge cases.

Mandatory Constraints

Examples of mandatory constraints include register number range constraints, instruction format alignment, and prevention of illegal instruction encoding.

These constraints ensure that the generated instruction streams strictly comply with the Instruction Set Architecture (ISA).

Differentiated Constraint Strategies

The framework employs differentiated constraint strategies based on instruction types:

Calculational instructions: Constrained within the valid register range according to the ISA spec and avoiding contaminating reserved registers in the environment Memory access instructions: In addition to the constraints of registers, it is also necessary to constrain the range of addresses and data synchronization between memory access instructions

Jump instructions: Strict control over jump ranges and protection of synchronization instructions and avoid jumping to illegal instruction segments.

Example Usage of APIs

Rapid stimulation Kernel Construction

By combining these APIs, users can quickly construct an ISA - based random kernel.

For example, generating a kernel with 8 load/store instructions, 80 computational instructions, and 8 branch instructions is fully randomized and automated.

02. High randomness

When generating a kernel through APIs, users only need to configure the interfaces they care about. For unconfigured interfaces, parameters will be randomly assigned within the legal range, and the instruction stream sequence will also reflect the high randomness

inherent in the APIS. 03. High flexibility

The use of APIs significantly simplifies the process of generating complex instruction streams. Users can define the scale and type of instructions they wish to randomize, leaving intricate details to the API's automated mechanisms

```
Code:
     repeat(8)
     add ldst instr(
           .ldst_instr_q({load_instr, store_instr}),
           .addr_reg(addr0),
           .offset addr(offset),
           .exception_insert(0));
```

The closed-loop mechanism of debugging

Debug data recording

This framework records the thread ID, global sequence number, operation type, and memory access address of memory access instructions during the instruction stream generation process.

This comprehensive memory access data record can accurately track and debug complex instruction streams.

Reverse-Tracing Mechanism

The debugging mechanism implements a reverse tracing mechanism for multi-threaded memory operations.

After detecting data errors at a specific address, the script quickly extracts the spatiotemporal context of all relevant instructions, allowing for precise backtracking to the first erroneous memory operation.

Visual memory access address delivery chain

This mechanism also visualizes the address data transfer chain across threads, providing a clear relationship between memory access instructions.

This helps diagnose complex issues such as cache consistency and memory access conflicts.

Example of debugging memory access address:

python3 find_transfer_chain.py

Enter M0/M1 address (hex): 1b7e69a4d2

Address type (m0/m1): m0
Access type (read/write): write
Complete Transfer Chain:

thread[5], dma_instr_5, dma_type=m0_to_m1, dma_len=15, len_id=18, read_m0_addr=b5e69a23d thread[5], dma_instr_5, dma_type=m0_to_m1, dma_len=15, len_id=18, write_m1_addr=1269 thread[0], dma_instr_9, dma_type=m1_to_m0, dma_len=9, len_id=0, read_m1_addr=1269 thread[0], dma_instr_9, dma_type=m1_to_m0, dma_len=9, len_id=0, write_m0_addr=1b7e69a4d2

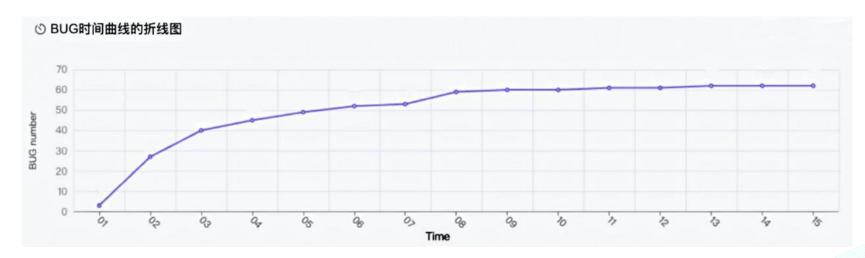

Experimental Validation and Conclusion

Experimental Results

Rapid Bug Detection

The random instruction streams constructed using APIs in the RIG environment uncovered 60+ bugs in the project.

60% of bugs were detected within the first two months of the verification cycle, with the Device Under Test (DUT) stabilizing around the six- month mark.

Identification of Undetected Bugs

The API- generated random instruction streams identified 3 bugs that were undetectable by module-level verification or semi-directed single-instruction-type stimulus.

These bugs required a mix of instruction types and sufficient randomness to manifest, proving the effectiveness of the stochastic approach.

Comprehensive Functional

Coverage

Functional coverage data collected over two weeks of regression testing shows that:

All instructions defined in the ISA SPEC were triggered.

Every instruction exercised the full register set.

Memory addresses covered boundary conditions and hardware-specific special addresses.

Jump instructions spanned all legal boundary ranges.

This confirms that the randomness of API- generated stimulus comprehensively covers the ISA specification and critical architectural

features.

Efficient Verification Framework

This paper presents an efficient systemlevel random verification framework for multi- threaded processors. It integrates four layers: Software Toolchain Layer, Instruction Set Abstraction Layer, Instruction Stream Randomization Layer, and Debugging Support Layer.

Key Innovations

The framework features modular instruction - type combinations through embedded APIs and an automated multi-thread conflict resolution mechanism. It also establishes a closed - loop debug support mechanism, significantly improving debugging efficiency and defect localization.

Significant Code Reduction

The framework demonstrates substantial improvements in multi-threaded instruction stream construction efficiency.

Users need only write 10+ lines of code to generate mixed stimulus streams containing 5,000-10,000 instructions, reducing code volume by over 90% compared to manual methods.

Future Work and Enhancements

Expanding Framework Capabilities

Future work includes expanding the framework's capabilities to support more complex instruction sets and processor architectures.

This will involve enhancing the API functions and constraint mechanisms to cover a broader range of verification scenarios.

Improving Debugging Tools

Further improvements to the debugging tools will focus on providing more detailed and intuitive error analysis.

This will help validation engineers quickly identify and resolve issues, further reducing verification cycles.

Enhancing Randomization Techniques

Continuous enhancement of randomization techniques will ensure comprehensive coverage of the instruction set architecture.

This will involve exploring new algorithms and methods to improve the randomness and effectiveness of instruction stream generation.

Thank You
